Abstract—This paper studies independent cascade models where influence propagates from seed-nodes along edges with independent probabilities. Upper-bounds for the expected number of influenced nodes were previously proposed using the spectral norm of a Hazard matrix. However, these bounds turn out loose in many cases, in particular with respect to sensitive edges such as bottlenecks, seed adjacent, and high probability edges. This paper proposes a similar bound that improves in such cases by handling sensitive edges more carefully.

I. INTRODUCTION

There is a broad range of applications for influence propagation which include determining a collective behavior on binary decisions [1], [2], [3], finding an effective strategy to vaccinate the disease [4], computing the transmission rate of a mobile ad-hoc network [5], studying the importance of individuals in spreading new ideas or products [6], characterizing the information diffusion in social network services [7], and studying the process for viral marketing [8].

Among various research questions related to the influence propagation, influence maximization problem—given a social network whose edges have the probabilities of influence between nodes, finding the top k seed nodes that maximizes the expected number of influenced nodes—has been widely studied. Kempe et al., [9] proposed a heuristic algorithm for this problem and many following studies also proposed various algorithms with improved accuracy and performance [10], [11], [12], [13].

One notable work taking a theoretical approach is the work [14] which finds the expected number of influenced nodes at the end of propagation (the influence) by proving an equivalence between bond percolation and a special case of Susceptible Infective Removed model [15] where all disease-transmission probabilities are equal. More recent theoretical works have also been focusing on estimation of the influence when a set of seed influencing nodes are given. Draief et al., [16] introduced an upper bound for the influence and tighter bounds were later suggested [17].

This paper shares the goal with mentioned works. We improve the upper bound for the influence in [17] by accounting the importance of bottleneck in the network. The proposed bound gives significant improvement, in particular, for stochastic block models and networks with small degrees. In addition, the result is supported by empirical data.

II. STOCHASTIC DIFFUSION MODELS

We briefly introduce the models commonly used in influence propagation, namely, stochastic diffusion models. Consider a network as a directed graph $G = (V, E)$ whose edges are assigned transmission probabilities, i.e. the probability that one end of the edge influences the other end. The influence propagation starts at the set $S_0 \subseteq V$ of seeds, the initially informed nodes. Then, the influence spreads with a random process, which defines different types of stochastic diffusion models. We next define two standard stochastic diffusion models.

Definition 1 (Independent cascade model). The model was defined in [18]. Let $G = (V, E)$ where $|V| = n$, $P$ be the $n \times n$ transmission probability matrix, and $S_0 \subseteq V$ be the set of initially influenced nodes. Then, the independent cascade model $IC(G, P, S_0)$ generates the active set $S_t$ for any discrete time $t \geq 1$ by the following process. First, set $S_t = S_{t-1}$ and for every edge $(i, j) \in \{ (u, v) \in E | u \in S_{t-1} \setminus S_{t-2}, v \in V \setminus S_{t-1} \}$, $i$ activates $j$ with probability $P_{ij}$. If $j$ becomes activated, add $j$ to $S_t$. The cascade stops if $S_T = S_{T+1}$ at the end of the activation process at time $T$.

In [18], it is proven that the independent cascade model is equivalent to the following model, live-arc graph model with independent arc selection.

Definition 2 (Live-arc graph model with independent arc selection). The model was defined in [18]. Let $G = (V, E)$ where $|V| = n$, $P$ be the $n \times n$ transmission probability matrix, and $S_0 \subseteq V$ be the set of initially influenced nodes. The live-arc graph model with independent arc selection $LI(G, P, S_0)$ generates the set of live edges $E_L$ as follows. For each $(i, j) \in E$, activate $(i, j)$ with probability $P_{ij}$. If $(i, j)$ becomes activated, add $(i, j)$ to $E_L$. Let $G_L = (V, E_L)$ be the subgraph of $G$. Then, the active set $S$ is the set of all nodes in $V$ that are reachable by $S_0$ in $G_L$.

Notations. For any live-arc graph model with independent arc selection $LI(G, P, S_0)$, we use random variable $X_i$ as the
Theorem 1. Let $i, j \in V$ be active, and $E_{ij}$ the edge between them. We have, for all $i \in V \setminus S_0$,

$$X_i = 1 - \Pi_{j \in S_0} (1 - X_j E_{ji}).$$

(1)

Recently, Lemonnier et al. proposed an upper bound for the influence $\sigma_N(S_0)$.

**Definition 3.** (17) For any seeded network $N = LI(G, P, S_0)$, the Hazard matrix $H$ and $H(S_0)$ are defined as

$$H_{ij} = \begin{cases} -\ln(1 - p_{ij}) & \text{if } (i, j) \in E \\ 0 & \text{otherwise} \end{cases}$$

and

$$H_{ij}(S_0) = 1_{j \not\in S_0} H_{ij}.$$

(2)

(3)

**Theorem 1.** (17) For any seeded network $N = LI(G, P, S_0)$ with $|S_0| = n_0 < n$, let $\rho(S_0)$ be the spectral radius of $H(S_0)$. Then, the expected number of nodes influenced by the seeds satisfies

$$\sigma_N(S_0) \leq n_0 + \gamma(n - n_0),$$

(4)

where $\gamma$ is the smallest solution in $[0, 1]$ of

$$\gamma - 1 + \exp \left( -\rho(S_0) \gamma - \frac{\rho(S_0)^n_{n_0}}{\gamma(n - n_0)} \right) = 0.$$

(5)

IV. IMPROVED BOUNDS

Note that the bound in Theorem 1 accounts for all solutions of the equation (1). However, some solutions are implausible. Consider a graph with two cliques $C_1$ and $C_2$, with node sets $V_1$ and $V_2$ respectively, where the cliques are connected to each other by a single edge $E_c$ and the seeds are on the clique $C_1$. Let all transmission probabilities be 1 except for $E_c$ where $p_c \neq (0, 1)$. When $E_c = 0$, $X_i = 1$, for all $i \in V_1$ and $X_j = 0$, for all $j \in V_2$. Hence, applying the upper bound on graphs with small cuts may result in substantial difference between the bound and the expectation.

Also, the bound does not consider for the fact that the edges near the seeds have more significant impact on the propagation. For example, in case of edges that are adjacent to the seeds being inactive, the only correct solution is $X_i = 0, \forall i \in V \setminus S_0$, but the equations in (1) also have other solutions which lead to a looser bound.

Finally, using the Hazard matrix in Definition 3 when at least one edge has transmission probability arbitrarily close to 1 gives a trivial bound, $n$, since $\rho(S_0)$ becomes infinite. In this section, we propose a tighter upper bound to improve these limitations.

A. Conditioning on a set of sensitive edges

We select a subset $S \subseteq E$ of edges and define the set of random variables $E[S] = \{E_{ij} | (i, j) \in S\}$. Note that

$$E[X_i] = \sum_{s \in \{0, 1\}^{|S|}} E[X_i | E[S] = s] \mathbb{P}(E[S] = s),$$

(6)

and

$$\sigma_N(S_0) = \sum_{s \in \{0, 1\}^{|S|}} \sigma_s(S_0) \mathbb{P}(E[S] = s),$$

(7)

where $\sigma_s(S_0) = \sum_i E[X_i | E[S] = s]$. Hence, we may compute upper bounds for $\sum_i E[X_i | E[S] = s]$ for all $s \in \{0, 1\}^{|S|}$ and average such bounds to find an upper bound for $\sigma_N(S_0)$.

Notice that if $S = E$, $E[X_i | E[S] = s]$ is a constant given the realization of the graph, but conditioning on $E$ requires $2^{|E|}$ computations. Thus, we select sensitive edges that potentially create a large difference between the bound and the expectation, such as edges in a bottleneck (small cut), adjacent to the seeds, or having high transmission probabilities.

B. Obtaining hazard matrix of conditioned graph

Condition $E[S] = s$ results in fixing the edge variables in $E[S]$ to either 0 or 1 according to $s$. Hence, the condition is equivalent to replacing the transmission probability matrix with $P'$ where $P'_{e'} = s_e, \forall e \in E$ and $P''_{e'} = P_{e'}, \forall e' \in E \setminus S$. However, as explained above, transmission probability 1 results in a trivial bound, $\sigma_N(S_0) \leq n$. Therefore, we modify the graph according to the conditioning, i.e. removing edges when they are set to inactive in the conditioning and contracting edges when they are set to active in the conditioning.

**Definition 4.** For any seeded network $N = LI(G, P, S_0)$, a subset $S \subseteq E$, and a realization $s$ of $E[S]$, the conditioned seeded network $N_s = LI(G_s, P_s, S_s)$ and the hazard matrix $H'_s$ are defined as follows.

- Let $L = \{L_1, \ldots, L_m\}$ where $L_i \subseteq V$ is a disjoint set of nodes that are merged together due to the contractions. For each $i \in [m]$, denote $u_i$ as the node obtained by merging all the nodes in $L_i$.
- $G_s = (V_s, E_s)$, where $G_s$ is obtained from $G$ by contracting the active edges and removing the inactive edges in $S$ according to the conditioning $s$, i.e. $V_s = (V \setminus \cup_{i=1}^m L_i) \cup \{u_i\}_{i=1}^m$, and let $|V_s| = n_s$.
- $S_s = \{u_i \cup \{u_i\}_{i=1}^m | S \cap L_i \neq \emptyset\}$, the set of nodes that are obtained by merging with at least one seed. Then, $S_s = (S \setminus \cup_{i=1}^m L_i) \cup S$, and let $|S_s| = m_s$.
- $P_s$ is obtained by computing the transmission probabilities of the edges in $E_s$.
The hazard matrix $\mathcal{H}'_s$ is defined as in Definition 3
\[
(H'_s)_{ij} = \begin{cases} 
-\ln(1 - (P_s)_{ij}) & \text{if } (i, j) \in E_s \\
0 & \text{otherwise}
\end{cases}
\]

Note that $\mathbb{E}[X_i|E[S] = s] = \mathbb{E}_{G_s}[X_i]$, where $i_s$ is the node resulting from merging $i$ with other nodes (possibly none) according to the conditioning $s$. Applying the bound from [17] on $G_s$, for all $i \in V_s \setminus S_s$,
\[
\mathbb{E}_{G_s}[X_i] \leq 1 - \exp(-\mathbb{E}_{G_s}[X_j])
\]

Definition 5. For any seeded network $N = LI(G, \mathcal{P}, S_0)$ and the conditioned seeded network $N_s = LI(G_s, P_s, S_s)$, define the vector $a = (a_s)_{i \in V_s}$, where $a_s = k$ represents that node $i$ in $G_s$ results from merging $k$ nodes in $G$, and call this the count vector.

Then,
\[
\sum_{i \in V_s} \mathbb{E}[X_i|E[S] = s] = \sum_{i_s \in V_s} a_s \mathbb{E}_{G_s}[X_{i_s}],
\]

since when $i_s$ is active, corresponding $a_s$ nodes in $G$ are active.

Definition 6. The modified hazard matrix $\mathcal{H}'_s$ of the conditioned graph $G_s$ with count vector $a$ is obtained from $\mathcal{H}'_s$ by multiplying $\frac{1}{\sqrt{\alpha_i}}$ to row $i$ and multiplying $\sqrt{\alpha_i}$ to column $i$ for every $i \in V_s$.

C. Improved bound

Theorem 2. In seeded network $LI(G, \mathcal{P}, S_0)$, for any set $S$ of edges, the expected number of nodes influenced by the seeds satisfies
\[
\sigma(S_0) \leq \sum_s (\gamma_s(n - n_s) + n_s) \mathbb{P}(E[S] = s)
\]

where $\gamma_s$ is the smallest solution in $[0, 1]$ of
\[
x - 1 + \exp(-\rho(S_s)x - \frac{\rho(S_s)m_s}{x(n - m_s)}) = 0,
\]
and $\rho(S_s)$ is defined as
\[
\rho(S_s) = \frac{\mathcal{H}_s(S_s) + \mathcal{H}_s(S_s)^T}{2}
\]

where
\[
\mathcal{H}_s(S_s)_{ij} = 1_{j \notin S_s \{H_s\}_{ij}}.
\]

Proof. For convenience, let $V_s = \{n_s\} = \{1, \ldots, n_s\}$. Define $Z_i = \sqrt{\alpha_i} \mathbb{E}_{G_s}[X_i]$, $Z = (Z_i)_{i \in [n_s]}$ and $u = (1_{i \notin S_s} Z_i)_{i \in [n_s]}$. Using [8],
\[
u Z = \sum_{i = 1}^{n_s} u_s \mathbb{E}_{G_s}[X_i]
\]

Let $w = (\sqrt{\alpha_i} u_i)_{i \in [n_s]}$. Then,
\[

\left(\sum_{i = 1}^{n_s} w_i \left(1 - \exp(-\mathbb{E}_{G_s}[X_j])\right) \right)
\]

\[
\leq |w|_1 \left(1 - \exp\left(-\mathbb{E}_{G_s}[X_j]\right)\right)
\]

Let $\mathcal{H}'_w$ be the matrix obtained by multiplying $\frac{1}{\sqrt{\alpha_s}}$ to $i$-th row of $\mathcal{H}'_w$ for all rows. Then,
\[
u Z = |w|_1 \left(1 - \exp\left(-\mathbb{E}_{G_s}[X_j]\right)\right)
\]

and by Cauchy-Schwarz inequality, $(u, b)^2 \leq (u, u)(b, b)$. Therefore,
\[
|w|_1^2 \leq (Z Z - m_s)(n - m_s),
\]

where $m_s = |S_s|$. The rest of the proof is a repeat of the one from [17]. Let $\rho_s(A)$ be the spectral radius of $\mathcal{H}_s(A) + \mathcal{H}_s(A)^T$ and $y = \frac{\nu Z}{|w|_1} = Z Z - m_s$. Then, by [17],
\[
|w|_1 \leq y(n - m_s).
\]

Then,
\[
y \leq 1 - \exp\left(-\rho_s(A)y - \frac{\rho_s(A)m_s}{|w|_1}\right)
\]

Consider a solution $\gamma_s$ in $(0, 1)$ of the equation
\[
x = 1 - \exp\left(-\rho_s(A)x - \frac{\rho_s(A)m_s}{x(n - m_s)}\right).
\]

Notice that $|w|_1 \leq \gamma_s(n - m_s)$ and $|w|_1 = \sum_{i \notin S_s} a_i \mathbb{E}_{G_s}[X_i]$. Thus,
\[
\sigma_s(A) = |w|_1 + m_s
\]

and
\[
\sigma(A) \leq \sum_s (\gamma_s(n - m_s) + m_s) \mathbb{P}(E[S] = s).
\]

It is important to compute $\gamma_s$ over connected graphs when condition $s$ results in creating more than one connected components.
We show that the bounds in Theorem 2 have significant improvement in the presence of sensitive edges.

In Figure 1, we consider a network $N_1 = LI(G_1, P_1, S_1)$, where $S_1$ contains a single seed $v_1$, randomly selected from $V(G_1)$, and all edges have the same transmission probabilities. The graph $G_1$ consists of two Erdős-Rényi random graphs with 100 nodes where edges are drawn with probability 0.2, and the two graphs are connected to each other by a single edge $e$. Notice that the edge $e$ (bottleneck edge) has a significant impact on the influence. Figure 1 compares the bounds given in Theorem 2 obtained by conditioning on the edge $e$ to the existing bounds from [17], for the transmission probability ranging from 0.1 to 0.9. We also provide the expected fraction of influenced nodes obtained by Monte Carlo simulation. The result shows that the bound of Theorem 2 is tighter than the existing bound introduced in [17].

Figure 2 considers a network $N_2 = LI(G_2, P_2, S_2)$, where $S_2$ contains a single seed $v_2$, randomly selected from $V(G_2)$, and all edges have the same transmission probabilities. The graph $G_2$ is an Erdős-Rényi random graph with 100 nodes where edges are drawn with probability 0.05. Figure 2 compares the bounds given in Theorem 2 obtained by conditioning on the seed adjacent edges to the existing bounds from [17], for the transmission probability ranging from 0.1 to 0.7. Since the bounds in Theorem 2 are often more computationally expensive than the bounds in [17], we also include an approximated version of the bounds. The approximated bounds take the conditioning $s$ from $\{0^{S_2}, 1^{S_2}\}$, i.e. one case where all edges in $S$ are active and the other where all edges in $S$ are inactive, and assign probability $1 - \Pi_{e \in S} (1 - p_e)$ to the first and $\Pi_{e \in S} (1 - p_e)$ to the second case. As shown in the Figure 2, the approximated bound for the experimented network is tighter than the bound in [17] across transmission probabilities greater than 0.2.

Figure 3 considers a network $N_3 = LI(G_3, P_3, S_3)$, where $S_3$ contains a single seed $v_3$, randomly selected from $V(G_3)$. The graph $G_3$ is an Erdős-Rényi random graph with 50 nodes where edges are drawn with probability 0.06. The transmission probability for each edge is drawn randomly from $\{0.1, 0.9\}$. The graph $G_3$ and the transmission probability matrix $P_3$ are drawn 100 times, and the points in the figure are the averages. Figure 3 compares the bounds given in Theorem 2 obtained by conditioning on the edges with high transmission probability to the existing bounds from [17], for the ratio of the high
transmission probability edges ranging from 0 to 0.5. Note that since transmission probability 0.9 results in trivial bound, we use the approximated bound instead. As shown in [17], the approximated bound for the experimented network shows a similar trend to the simulated result, whereas the bound in gives almost trivial bound.

VI. CONCLUSION

In this paper, we propose upper bounds for the expected number of influence nodes in independent cascade models. The bounds improve the bounds in [17], in particular, in the presence of sensitive edges, such as bottlenecks, seed adjacent, and high probability edges. We also present approximated bounds with low computational complexity. Finally, the results are supported by empirical data.
